Macrozooplankton and Small Nekton in the Coastal Waters Off Vancouver Island (Canada) and Washington, Spring and Fall of 1963

By

DONALD S. DAY, Oceanographer

National Marine Fisheries Service Biological Laboratory
Seattle, Washington 98102

ABSTRACT

Eight species of euphausiids, 5 species of mysids, and 14 species of fish were identified. Euphausiids composed about 90 percent by number of the organisms caught, and fluctuations in their abundance were concomitant with changes in the biomass of the samples. The bulk of the organisms collected at night were in the upper 30 m. All species were taken by a 0.9-m. Isaacs-Kidd midwater trawl.

The concentration of organisms was lowest near shore, reached a maximum at or near the outer edge of the continental shelf, and decreased again farther offshore. The concentration of organisms was greater in the southern part of the region than in the northern part. This distribution was apparently related to the general surface circulation. Seasonal fluctuations were indicated by a decrease in biomass from spring to fall.

INTRODUCTION

Predictions of the location and abundance of commercial fishes that depend on plankton for food can be improved by a knowledge of the distribution and numbers of plankton within large regions of the sea. The waters over the continental shelf and slope along the west coast of the United States and Canada appear to be one of the world's highly productive marine environments (Reid, 1962). Little is known, however, about the distribution and composition of the macrozooplankton and small nekton inhabiting the region off the coasts of Vancouver Island, British Columbia, and the State of Washington. Aron (1959, 1962) reported on the abundance and distribution of oceanic macrozooplankton and small nekton in the northeastern Pacific Ocean during the summer of 1957 and the summer and early fall of 1958, but he obtained only a few samples in the coastal region. Pearcy (1964) and Pearcy and Laurs (1966) studied the seasonal composition, distribution, and migration of the mesopelagic fishes over the continental terrace off the Oregon coast. The taxonomy and distribution of euphausiids in the Pacific Ocean has been studied by Banner (1949); Boden, Johnson, and Brinton (1955); Brinton (1962a); and Hebard (1966). Banner (1947, 1948) investigated the taxonomy and distribution of the mysids in the northeastern Pacific Ocean.

In spring and fall 1963 during oceanographic cruises of the RV George B. Kelez (Ingraham, 1967), macrozooplankton and small nekton were collected within 185 km. of shore from Cape Cook on Vancouver Island to Willapa Bay, Wash. The purpose of my report is to show the abundance, distribution, and composition of these organisms over the continental shelf and slope.

METHODS

A 0.9-m. Isaacs-Kidd midwater trawl (Isaacs and Kidd, 1953; Aron, 1962) was used to sample the animal population. The body and throat of the net were constructed from 64-mm. (stretched measure) cotton netting with a liner of 13-mm. bait netting in the throat (fig. 1). The cod end was a nylon plankton net of 3-mm. mesh with a mouth 1/2 m. in diameter.

Collections were obtained from May 3 to May 16 (79 samples) and from October 28 to November 22 (60 samples) along lines perpendicular to the coast. Four lines of stations were spaced about 111 km. apart during the spring cruise (fig. 2), and nine lines of stations were spaced about 56 km. apart during the fall cruise (fig. 3). Stations were located near the 55-, 183-, 914-, 1,829-, and 2,377-m. depth contours on each line except line V, where all stations were near the 183-m. depth contour. An additional station at the 119-m. depth contour was sampled during the fall cruise on lines II, III, IV, VI, VII, and VIII.

During the lowering, towing, and retrieval of the net, the speed of the vessel was maintained at 3 to 4 knots. Depth of the trawl was based on a 4:1 ratio for wire length to depth, established by repeated lowerings of the trawl with a bathythermograph attached to the depressor. Depths are believed to be accurate within $\pm$20 m. at a depth of 150 m. and $\pm$8 m. at 30 m. The average length of time for lowering and retrieving the net from the sampling depths was: 7 minutes for 150 m., 3 minutes for 75 m., 1 minute for 30 m., and less than 1 minute for 20 m. or shallower. Additional information on the towing characteristics of similar gear is given by Aron, Raxter, Noel, and Andrews (1964). The catches probably included animals from water above the sampling depths, because the net was open throughout the tows.

Samples were obtained from shallow oblique tows (30 m. to the surface) at each station during both cruises (appendix tables 1 and 2). In addition, samples from deep oblique tows (150-30 m.) were taken at stations where the bottom depth was 914, 1,829, or 2,377 m. during the spring cruise (appendix table 1). All tows were made between 1 hour after sunset and 1 hour before sunrise. Tows were made in steps: for the shallow tows, 8 m. of cable were retrieved every 2 minutes for 15 steps; and for the deep tows, 16 m. of cable were retrieved every minute for 30 steps until 120 m. of cable remained in the water. This remaining length of cable was retrieved as rapidly as possible, usually within 1 minute. Thus, the duration of the tows was 30 minutes from the time the net reached maximum depth until it was at the upper limit (surface or 30 m.) of the depth interval.

Horizontal tows were taken at two stations during the spring cruise to provide information on vertical movement of organisms in the upper 150 m. (appendix table 3). At station 8, samples were obtained at dusk, midnight, dawn, and afternoon during a 24-hour period at the surface and depths of 15, 30, 75, and 150 m. (Because of equipment failure, samples were collected at 4:00 p.m. instead of "noon.") At station 17, samples were taken at dusk, midnight, dawn, and noon, at the surface and depths of 10, 20, 30, 75, and 150 m. At both stations, the net was at the specified depth for 10 minutes.

At the laboratory, water was removed from the samples by filtering through nylon cloth having about 1.5-mm. mesh. Fish and medusae larger than 1 cm. were removed, and the remainder of the sample was weighed with an accuracy of $\pm$0.1 g. The volume of each filtered sample was determined by displacement of 5-percent Formalin in a graduated cylinder. The values for weight and volume had a correlation coefficient of 0.99. In this paper, weight is used as the measure of biomass. Samples of more than 30 g. were subdivided by a Folsom plankton splitter (McEwen, Johnson, and Folsom, 1954) so that the subsamples contained about 400 organisms. The organisms from

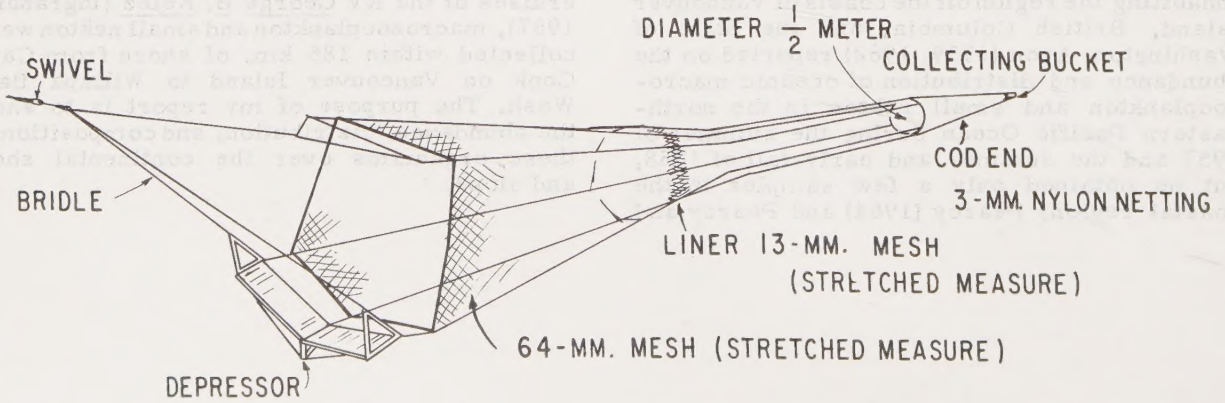

Figure 1.--The 0.9-m. Isaacs-Kidd midwater trawl.

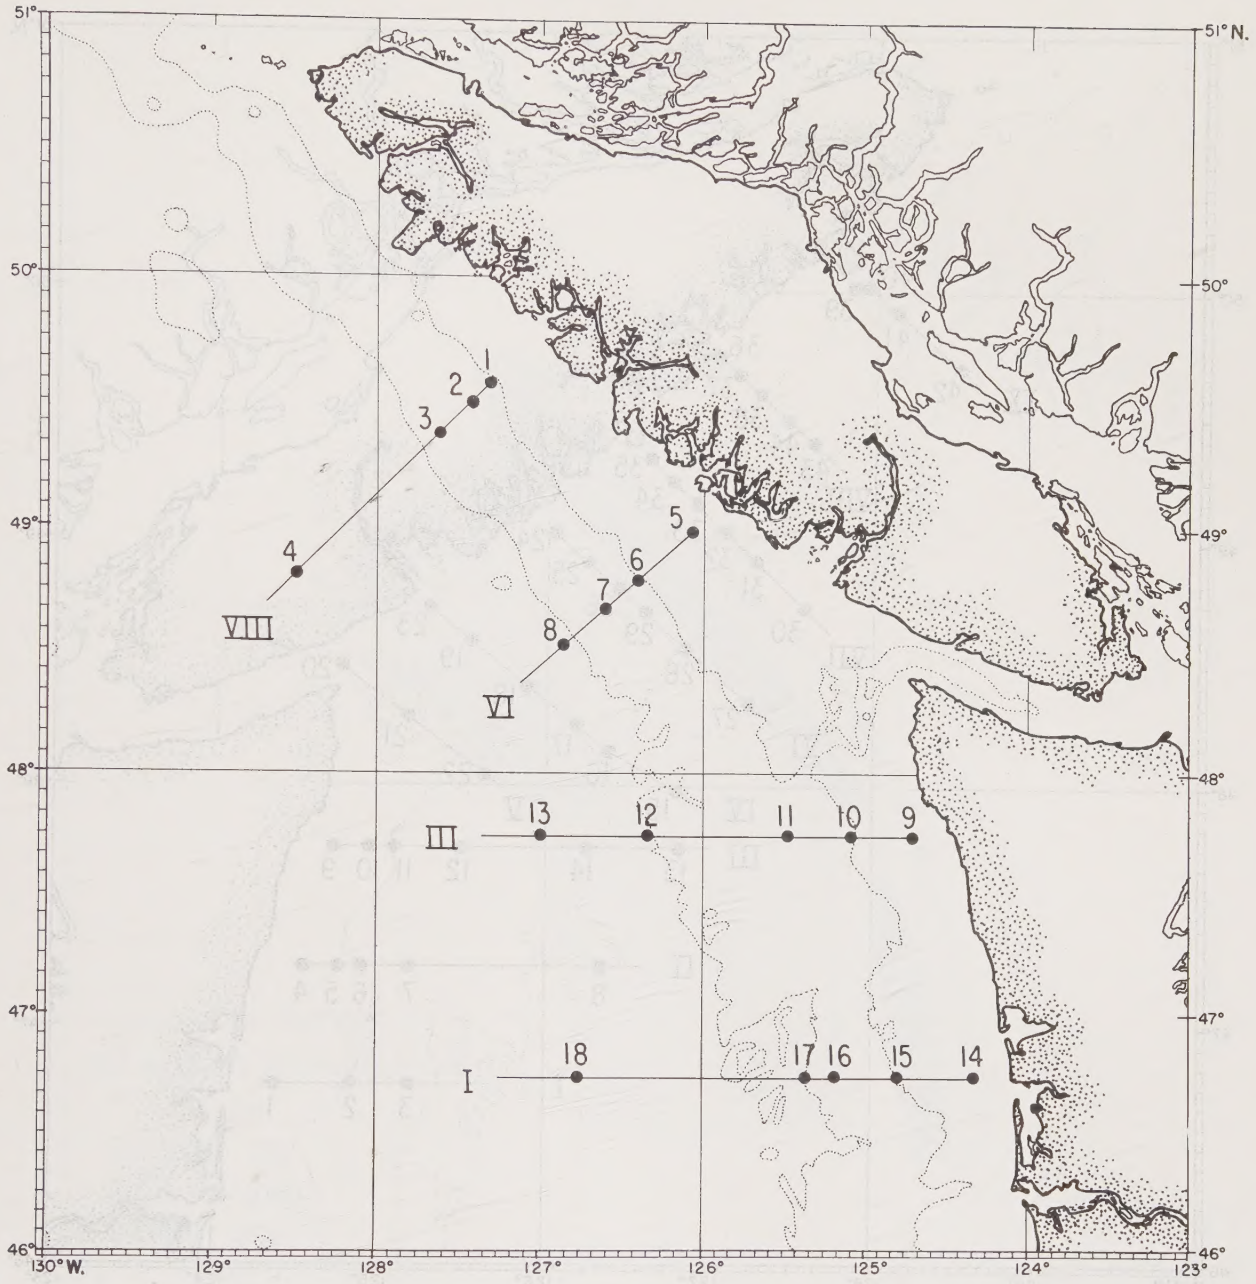

Figure 2.--Station locations, spring 1963. (The 183- and 1,829-m. depth contours are shown.)

these subsamples and the remaining samples were sorted according to taxonomic groups and counted (appendix tables 1, 2, and 3). Species of euphausiids, mysids, and fish were identified and their distributions are discussed in the following sections.

To evaluate sampling variability, four replicate shallow and deep oblique tows (four samples in each interval: surface to 30 m. and 30-150 m.) were made during the spring cruise at station 12 and two replicate shallow tows were made at most stations on lines III, VI, and VII during the fall cruise (total of 30 samples). Averaged coefficients of variation for the wet-weight values (computed from the replicate tows) were used as criteria for judging the significance of areal differences in the biomass values (figs. 4 and 5). The coefficients were 28 percent in spring and 46 percent in fall for the shallow tows, and 17 percent in spring for the deep tows.

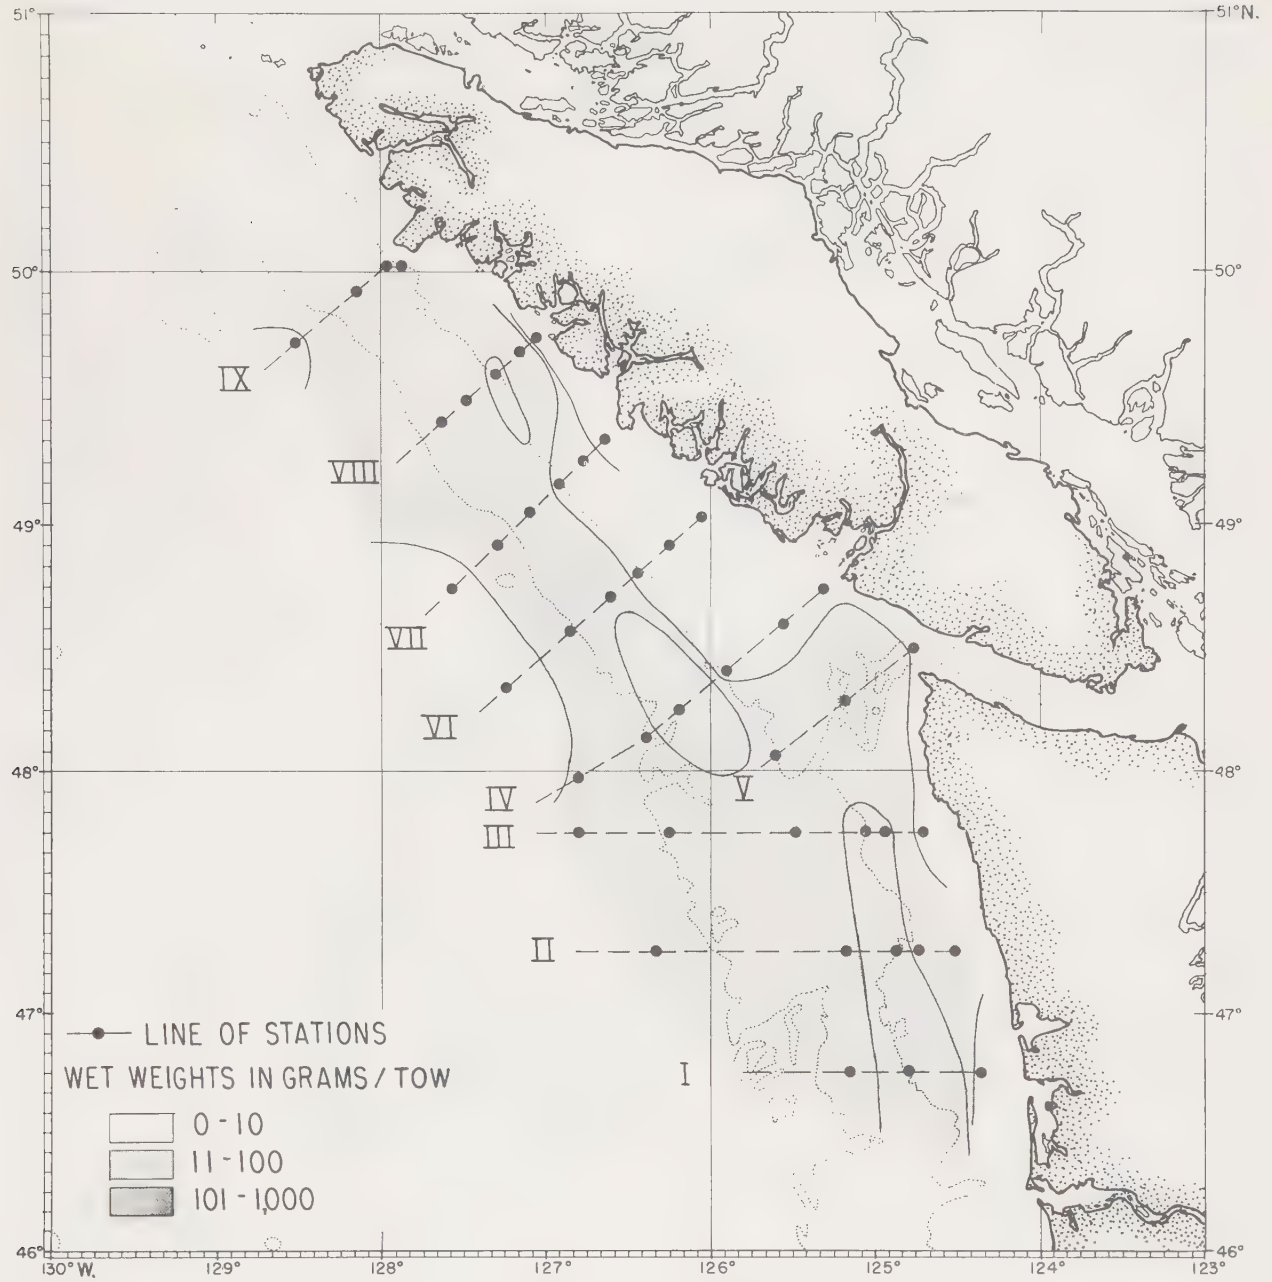

Figure 5.--Distribution of biomass as determined by shallow oblique tows (surface to 30 m.), fall 1963. (The 183- and 1,829-m. depth contours are shown.)

GEOGRAPHIC DISTRIBUTION

The quantity of macrozooplankton and small nekton that were taken within the upper 30 m. of the water column varied substantially in the study area both seasonally and geographically. The relative abundance of macrozooplankton within the study area and possible reasons for variations in their distribution are described in the subsequent sections on biomass and major taxonomic groups.

BIOMASS

The biomass in the surface layer, estimated from the shallow oblique tows, was considerably greater in the spring than in the fall. In both seasons abundance varied widely seaward from the coast and from north to south along the coast. Along lines perpendicular to the coast, the biomass was minimal nearshore, reached a maximum at or near the outer edge of the continental shelf (183-m. depth contour), and decreased again farther offshore (figs. 4 and 5). The only exceptions to this general distribution were in the fall along line V, where all stations were located at the 183-m. depth contour near the Juan de Fuca Canyon, and along line VIII, where the biomass reached a maximum over the 119-m. depth contour, decreased to a minimum at 183 m., and then increased seaward. Neither the distributions of surface temperature and salinity, nor currents provide an immediate explanation for this general pattern. Similar distributions have been reported by Mednikov (1958) for the Kurile-Kamchatka region of the northwestern Pacific Ocean and by St. John (1958) for the Cape Hatteras region of the northwestern Atlantic Ocean.

The greatest biomass was found in the southern part of the region. The boundary between relatively high and low biomass was between lines VI and VIII in spring, and shifted about 111 km. to the south, between lines IV and VI, in fall.

The distribution of biomass was similar to the general features (Ingraham, 1967) of the surface circulation (surface to 200 m.). Low biomass coincided with a distinct onshore movement of offshore water near the middle of Vancouver Island (figs. 6 and 7). Biomass was high where the circulation was characterized by eddies or reduced flows off the coasts of Washington and southern Vancouver Island. There was no evidence of continuous northward flow of near-shore water along Vancouver Island north of lat. 48 N. (Ingraham, 1967).

TAXONOMIC GROUPS

The seasonal and geographic changes in the distribution of biomass were examined relative to the distribution of the most important taxonomic groups. Euphausiids were of primary concern since they contributed the largest numbers to the biomass.

Euphausiids

Eight species of euphausiids were identified: Euphausia pacifica, Thysanoessa spinifera, T. longipes, T. raschii, Tessarabrachion oculatus, Nematoscelis difficilis, Nematobrachion flexipes, and Stylocheiron maximum. These species constituted 90 percent, by number, of the total catch (figs. 8 and 9). E. pacifica and T. spinifera were the most abundant euphausiid species, contributing 76 and 14 percent, by number, of the organisms collected (figs. 10-13). The differences in biomass from north to south (figs. 4 and 5) were evidently related to the distribution of E. pacifica (figs. 10 and 11). Ninety-five percent of the E. pacifica, by number, were collected from the area of high biomass. T. spinifera was usually more prominent, relative to the total catch, where the abundance of E. pacifica was low.

The record of seasonal changes in abundance and composition of euphausiids (tables 1 and 2) indicate larger numbers of E. pacifica in spring than in fall by a ratio of about 2 to 1. Numbers of T. spinifera increased slightly but their percentage of the total catch increased markedly during the same period (table 1). The substantial decrease in abundance of E. pacifica accounted for most of the reduction in biomass from spring to fall.

The seasonal decrease in biomass was also influenced by the presence of larger specimens of E. pacifica and T. spinifera in spring than fall. Brinton (1962b) stated that E. pacifica may live as long as 2 years and spawn at least twice and that two size-classes spawn off central California in a period from April to June: (1) males 13 to 14 mm. and females 13 to 16 mm., and (2) males 17 to 19 mm. and females 18 to 24 mm. If these size-classes represent age-groups I and II, E. pacifica collected in spring (fig. 14) were primarily of age-group II while most of the catch in fall was of age-group I, with only a remnant of age-group II. The similarity in seasonal shift in the modal size of T. spinifera (fig. 15) and E. pacifica (fig. 14) suggests similar seasonal age-class composition of the two species. Because the mesh in the 0.9-m. midwater trawl did not retain euphausiids smaller than 10 mm., the O age group could not be evaluated.

Seasonal abundance and dominant species of euphausiids were grossly different offshore from the 914-m. contour, south of the Strait of Juan de Fuca. E. pacifica was dominant in spring, but T. spinifera dominated or shared dominance with E. pacifica in the fall (figs. 10-13). Numbers of E. pacifica were relatively

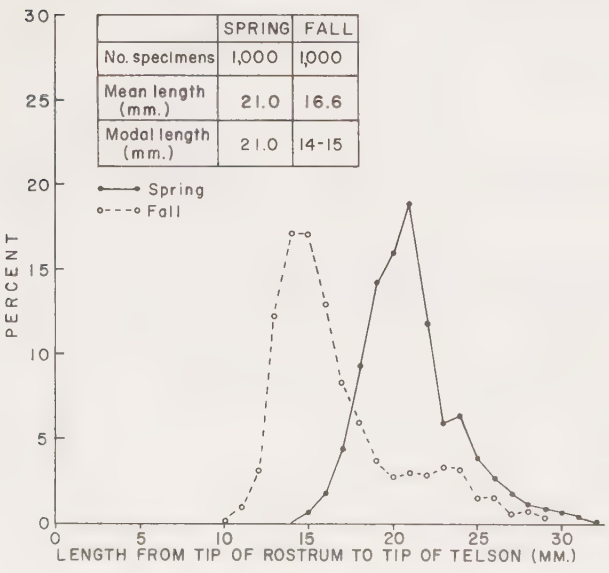

Figure 15.--Size distribution of Thysanoessa spinifera off Vancouver Island and Washington in spring and fall, 1963.

large in spring but much smaller in the fall. Conversely, numbers of T. spinifera were significantly larger in the fall than in the spring. This increase in abundance of T. spinifera may be associated with upwelling that occurs during summer off Washington and Vancouver Island (Doe, 1955). The high abundance of T. spinifera in the southern part of its range has been associated with centers of upwelling by Brinton (1962a).

Of the remaining euphausiid species, N. difficilis was found in significant numbers only in the fall at stations 27 and 28 where it constituted 31 and 27 percent, respectively, of the total euphausiid catch and included egg-bearing females. T. raschii was taken only at station 20 in the mouth of the Strait of Juan de Fuca. Other species appeared only sporadically in the samples.

Other Groups

Larval and postlarval benthic fishes were identified as belonging to the families Cottidae, Scorpaenidae, Hexagrammidae, Liparidae, Pleuronectidae, and Agonidae. Fourteen species of mesopelagic, epipelagic, and neritic fish were identified (table 3).

Mesopelagic fishes were numerous over the continental slope but were not collected over the shelf (table 4). They were in only 2 of 18 samples along the outer edge (183 m.) of the shelf (station 1 in spring and station 39 in fall). Pearcy (1964) found a similar distribution of mesopelagic fishes over the continental slope and shelf off the coast of Oregon.

[1] Scientific name has been changed to Protomyctophum crockeri.
[2] Scientific name has been changed to Symbolophorus californiensis.
[3] Scientific name has been changed to Stenobrachius leucopsarus.

Mysids were caught only in fall at the nearshore stations south of line VI. Five species were identified: Neomysis kadiakensis, N. rayii, N. americana, Acanthomysis macropsis, and A. columbiae. N. kadiakensis was the dominant mysid except at station 20 at the mouth of the Strait of Juan de Fuca. N. rayii was at only two stations; it was the dominant mysid at station 20 but contributed only about 3 percent, by number, to the total mysid catch at station 23. The limited distribution of N. rayii was similar to the distribution of the euphausiid, Thysanoessa raschii.

VERTICAL DISTRIBUTION

The quantity of macrozooplankton and small nekton that were taken at various depths within the upper 150 m. of the water column differed diurnally and between sampling locations. The relative abundance of macrozooplankton and small nekton within the water column are described by the distributions of biomass and major taxonomic groups.

BIOMASS

Vertical distribution was investigated in the present study to determine the depths of maximum abundance within the upper 150 m. throughout 24-hour periods. During the spring cruise at stations 8 and 17, horizontal tows were taken at dusk, midnight, dawn, and noon or afternoon within 24-hour periods. The use of a net with an opening and closing mechanism would have provided better resolution of the depth distribution in any one sample, but some generalizations can be made from data obtained with an open trawl. The must larger quantities of organisms collected in the upper 150 m. at dusk, midnight, and dawn than in the afternoon (station 8) or at noon (station 17) indicated an apparent diurnal vertical migration to depths in excess of 150 m. (figs. 16 and 17).

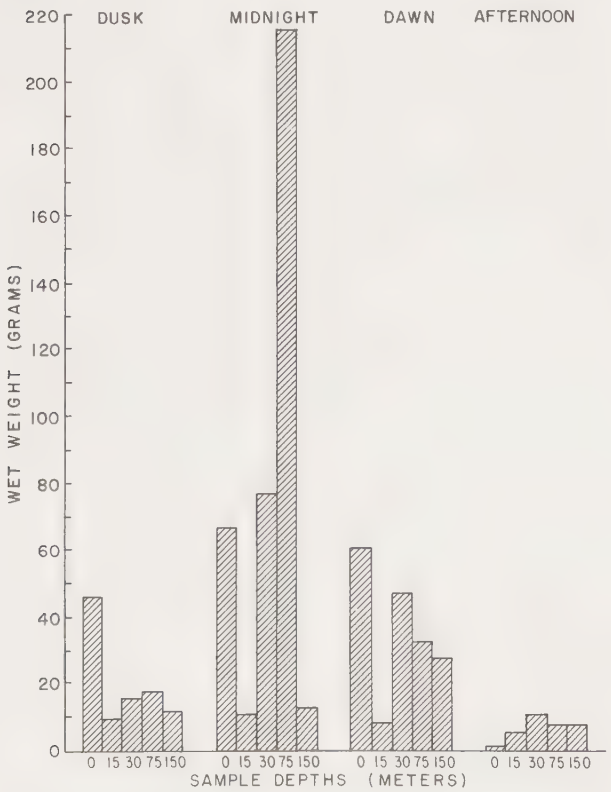

Figure 16.--Distribution of biomass by time of day and depth, at station 8, spring 1963.

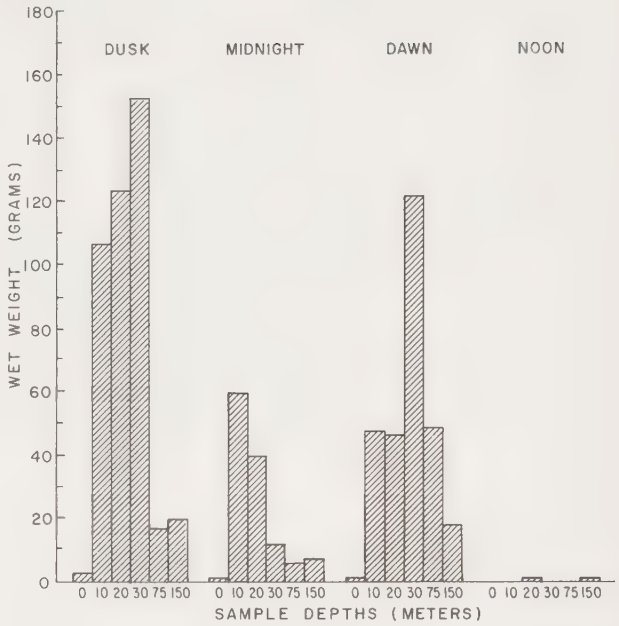

Figure 17.--Distribution of biomass by time of day and depth, at station 17, spring 1963.

Additional information on the nighttime vertical distribution of the biomass was provided by samples from oblique tows near the 914-, 1,829-, and 2,377-m. depth contours during the spring cruise. The well-mixed surface layer was sampled by towing obliquely through the upper 30 m. Tows from 150 to 30 m. were taken to sample the layer from the base of the halocline through the thermocline. Most of the organisms were collected in the surface layer at all stations except station 7 (fig. 18).

TAXONOMIC GROUPS

Distributions of the most important taxonomic groups were examined in relation to time of sampling and some oceanic features. Euphausiids and crab larvae were of primary concern since they contributed the largest numbers to the biomass.

Euphausiids

In the spring some gross differences were apparent in the nighttime vertical distribution of several euphausiid species. Most E. pacifica and T. spinifera were caught in the shallow oblique tows, whereas T. oculatus was most abundant in the deep oblique tows (table 5).

Catches from horizontal tows at stations 8 and 17 indicated that euphausiids were rare at the surface throughout the 24-hour sampling periods. At dusk, midnight, and dawn, the

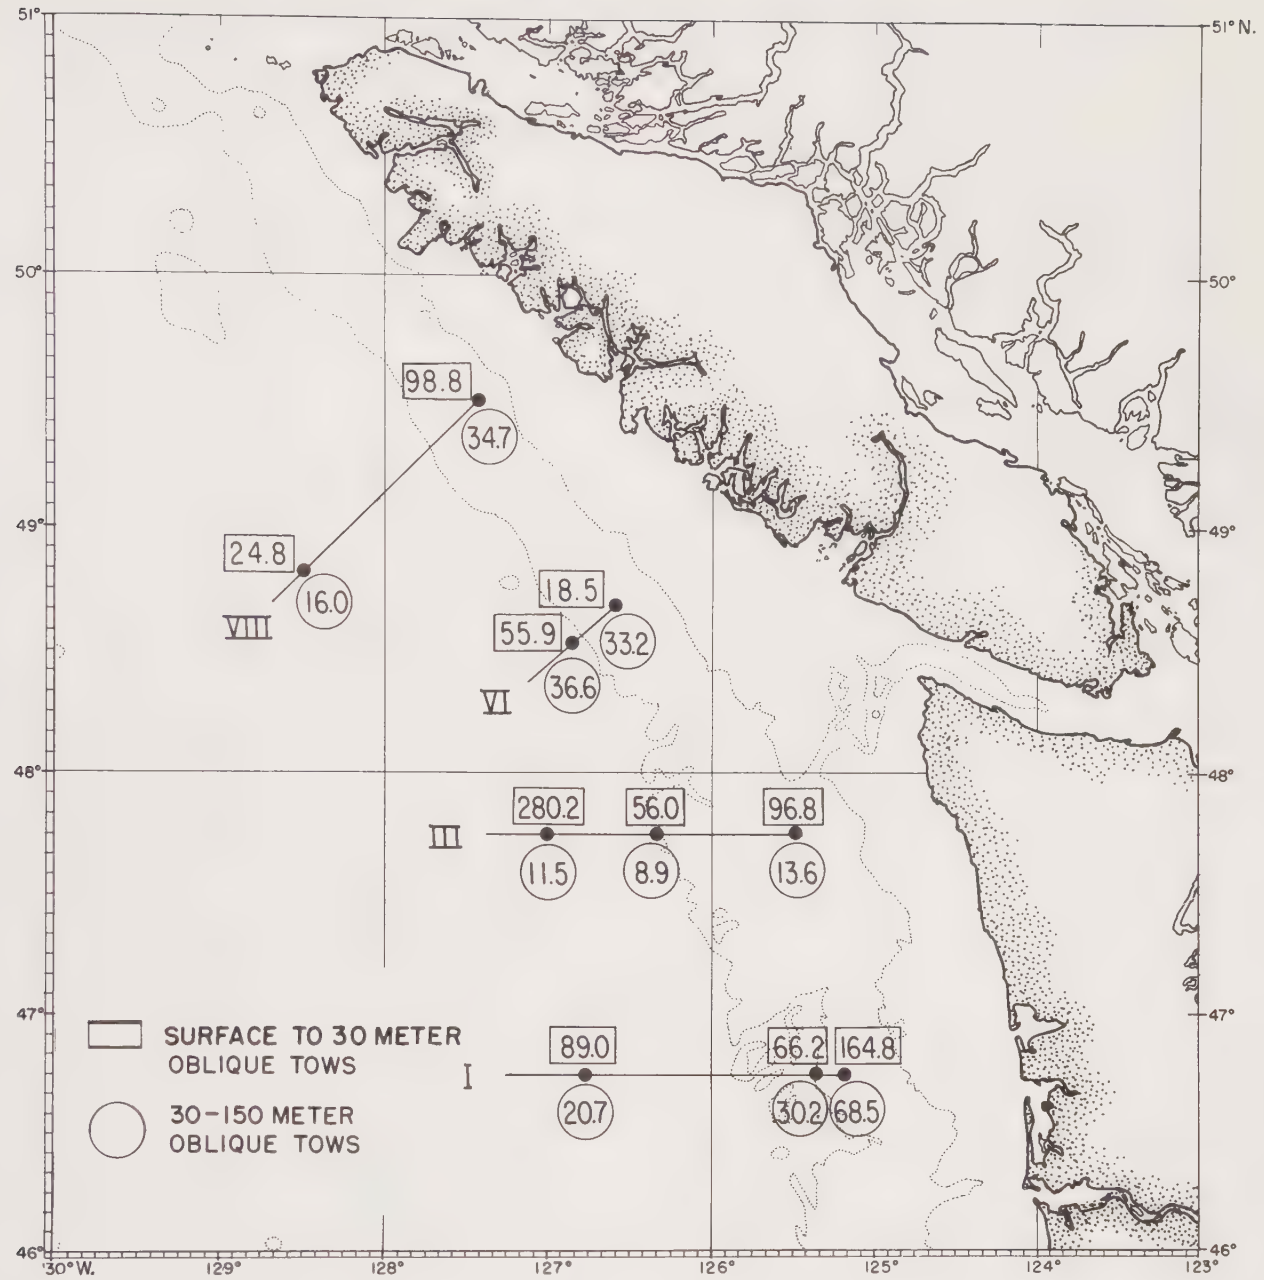

Figure 18.--Distribution of biomass in spring 1963 as wet weight in grams per 30-minute tow. (The 183- and 1,829-m. depth contours are shown.)

largest numbers occurred at 30 m. at station 8, and within the upper 30 m. at station 17 (table 6). These slight differences in distributions may have been affected by the bright moonlight during the sampling at station 8 and the absence of moonlight at station 17.

All euphausiids, with the possible exception of T. longipes were more numerous in the upper 150 m. during dusk, midnight, and dawn than at noon or afternoon. T. longipes showed evidence of vertical migration at station 17, but not at station 8 (table 7). Differences in sampling time and vertical distribution of temperature and salinity at these two stations may have affected the differences in distribution. T. longipes was found in the upper 150 m. during the afternoon at station 8, where a well-mixed surface layer, about 60 m. thick, existed above a sharp thermocline; it was not taken at station 17 at noon where these physical features were missing (fig. 19). Brinton (1962a) noted that the vertical movements of

T. longipes in the northern part of their range were different from those farther south.

The vertical distribution and migration of some of the euphausiid species differed slightly from the description by Brinton (1962a). He stated that T. spinifera was restricted to depths of less than 100 m. and showed no evidence of diurnal vertical migration, whereas we did not take adults of this species in the upper 150 m. of the water column during noon or afternoon periods. The absence of adults may indicate vertical migration or avoidance of the trawl by the animals. Brinton also found N. difficilis common in the upper 140 m. and no clear evidence of diurnal vertical migration. There was slight evidence for such movements at station 17 (table 7), however.

Other Groups

At dusk, midnight, and dawn, a substantial part of the biomass was collected at the surface at station 8 but not at station 17 (figs. 16 and 17). At station 8, the largest catch, taken from 75 m. at midnight, contained at least seven times as many crab larvae (Cancer sp.) as any of the other samples. The surface samples taken at dusk, midnight, and dawn contained 74 to 94 percent crab larvae, by number. Large concentrations of crab larvae and euphausiids were not found at the same depths (tables 6 and 8), but large numbers of crab larvae and postlarval benthic fishes (table 9) were caught together at dusk, midnight, and dawn. The fishes were from the families Scorpaenidae and Cottidae.

Tarletonbeania crenularis was the only species of mesopelagic fish collected in large numbers at stations 8 and 17. About 84 percent of the total catch was taken at the surface (table 10). Similarly, Pearcy (1964) found high concentrations of this species at the surface off the coast of Oregon.

SUMMARY

1. Plankton samples from the upper 150 m. of the water column were collected in coastal waters off Vancouver Island, British Columbia, and the State of Washington in spring and fall 1963, by towing a 0.9-m. Isaacs-Kidd midwater trawl.

2. The biomass was composed of about 90 percent euphausiids, of which 76 percent, by number, were Euphausia pacifica and 14 percent were Thysanoessa spinifera.

3. Biomass was generally lowest near shore, reached a maximum at or near the outer edge of the continental shelf, and decreased again farther offshore.

4. Biomass was significantly higher in the southern part of the region than in the northern part.

5. Macrozooplanktonic and small nektonic organisms were much more abundant in the spring than in the fall. The change in biomass resulted principally from the large decrease in numbers of Euphausia pacifica and the decrease in size of E. pacifica and Thysanoessa spinifera from spring to fall.

6. Mesopelagic fishes were numerous over the continental slope but were found only occasionally at the edge of the shelf. None were caught over the continental shelf.

7. Most of the macrozooplanktonic and small nektonic organisms appeared to undergo a diurnal vertical migration of at least 150 m. at the two stations where horizontal tows were made. All the euphausiid species showed greatly diminished numbers or were completely absent from the surface to 150 m. during the day at these two stations except Thysanoessa longipes, which was found in the upper 150 m. during daylight only at the station with a sharp thermocline and well-mixed layer. Most of the macrozooplankton and small nekton were in the surface to 30-m. rather than the 30- to 150-m. interval at night.

8. Large concentrations of crab larvae and postlarval benthic fishes were taken at the surface and 75 m., but euphausiids were not abundant at these depths. The mesopelagic fish, Tarletonbeania crenularis, was caught primarily at the surface.
